ACKNOWLEDGMENTS

The expertise provided by Shawn Sculley in the statistical analysis was invaluable for the completion of this project. Medardo Molina provided a thorough review of the technical aspects of this investigation. Tom MacVicar supplied valuable suggestions for analyzing and presenting the final results. Barbara Brown should be recognized for her tremendous effort in the actual retrieval and analysis of the enormous amount of daily rainfall record that was processed, as well as Terrie McRorie for her excellent work digitizing the isohyetal map. Nettie Winograd is credited for her fine job typing and editing this report. Finally, special thanks to those that reviewed this analysis.

I. INTRODUCTION

The South Florida Water Management District (District) is committed to maintaining the most accurate and up-to-date rainfall frequency data for use in evaluating permit applications submitted to the District. The *Frequency Analysis of Rainfall Maximums for Central and Southern Florida, Technical Publication 81-3 (MacVicar,1981)* presents the results of a comprehensive frequency analysis of maximum rainfall events of 1-, 2-, 3- and 5-day duration along with seasonal and annual durations. The 1- and 3-day duration maximum rainfall events are the most commonly considered by the District's Regulation Department in the permit review process described in the *Management And Storage of Surface Waters, Permit Information Manual, Volume IV (1989)*. The purpose of this report is to update the 1- and 3-day duration frequency analysis included in the Permit Information Manual with the additional data that has become available in recent years. This data allows for additional gages to be added to the analysis while also increasing the reliability of long-term existing gages that were used in the earlier study. Refined and more stringent criteria have been developed to determine whether a particular station year should be used. Only station years that have a 90 percent probability of including the annual maximum event in the observed values were included. Even with these stricter criteria, the number of stations used in the analysis increased from 140 in the earlier analysis to 156 in this analysis. The number of station-years increased from 4,606 to 5,587, or by 21 percent.

The density of rain gages increased the greatest in the Kissimmee River Valley where only sparse data was available for the earlier study. A few gages were eliminated due to more strigent criteria used in selecting the station-years to be analyzed.

II. DATA SOURCES

The sources of data for this study include all the rainfall gages within or near the District for which at least 20 years of quality daily record is available. The data was obtained from the same sources used in the 1981 analysis. These include data that were obtained from the Weather Bureau Records, the South Florida Water Management District, the Lake Worth Drainage District, and the Corps of Engineers. The data that became available in recent years facilitates the production of rainfall frequency maps for South Florida using a higher quality and denser network of rain gages than those used in the earlier study. Figure 1 illustrates the areal distribution of these rain gages along with an indication of the number of years of reliable record at a particular station. More specific information about the rainfall gages will be found in the appendix.

The majority of the rainfall values represent gage readings taken once a day. The time of day that readings are taken varies between stations. In certain cases, hourly values are summed over 24-hour periods to obtain the daily values. No attempt was made to adjust all the daily data to the same 24-hour period, or to estimate maximum 24-hour rainfall from observational daily measurements. No adjustments for bias due to gage type or exposure were made. This analysis was based completely on the daily observations, as was the original analysis completed by the District in 1981.

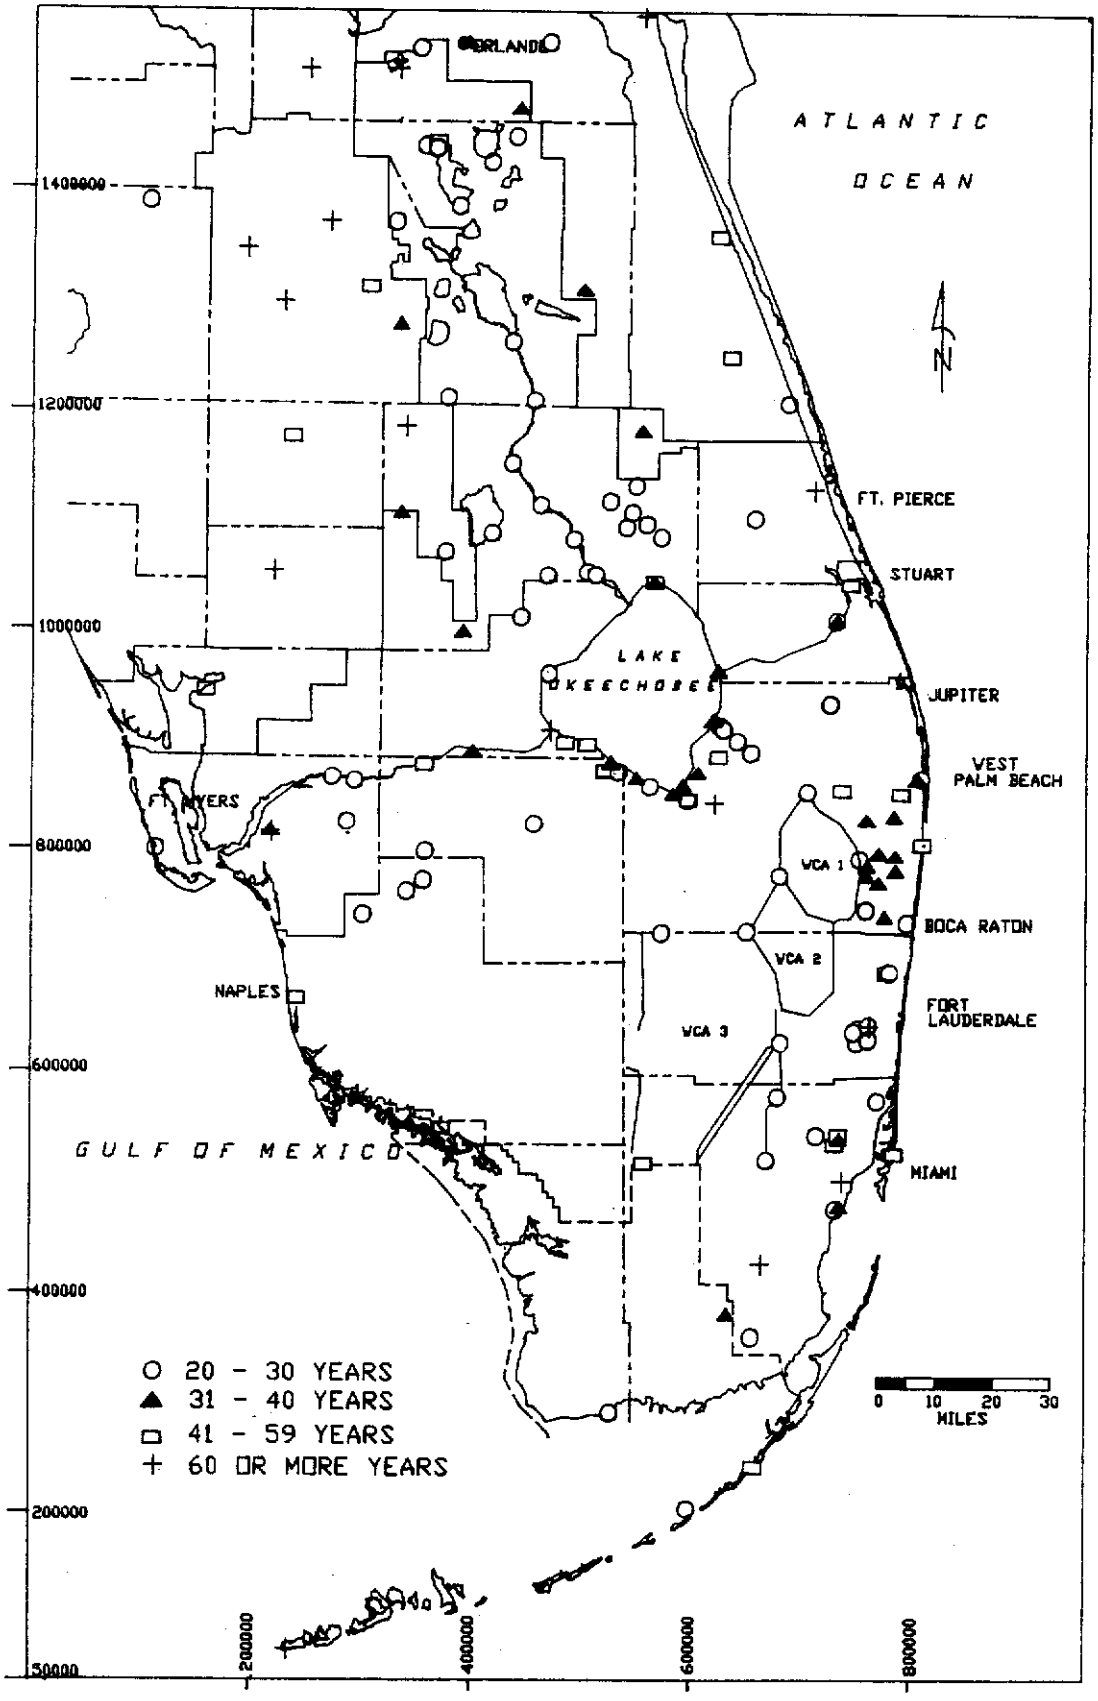

Figure 1. Rainfall Gauge Location

III. DATA PREPARATION

Each year of data is assumed to represent an independent event at that location. A filler technique similar to that used in the previous analysis was used to estimate rainfall at stations that contained missing record. This linear interpolation scheme uses the ratio of the average annual precipitation at nearby stations to that at the station with missing record to determine a weighting factor between the rainfall at the nearby stations and the one with missing data. Then the missing rainfall value may be estimated by the relationship

$$P_x = \frac{1}{N} \sum_{i=1}^{N} \frac{M_x}{M_i} * P_i$$

where

P_x is the estimated daily precipitation at the station with missing record,
M_x is the average annual precipitation at the station with missing record,
M_i is the average annual precipitation at ith nearby station,
N is the number of nearby stations used for estimate,
P_i is daily precipitation at the ith nearby station.

This method is known as the normal ratio method (Paulhus and Kohler, 1952).

Certain stations have accumulated rainfall totals during weekends and holidays. These stations may otherwise have reliable daily records. It is desirable to include these records in the analysis. An accumulated rainfall total was distributed over the individual days during which the rainfall was accumulated based on the temporal distribution of rainfall at the nearby stations that had daily record available. The relationship used to estimate the daily rainfall was the same as for the missing rainfall with the exception that the annual mean rainfall values M_x and M_i are replaced by the accumulated values A_x and A_i. Again, the subscript x refers to the rainfall station that the value is being estimated and the subscript i refers to the ith of n stations used to estimate the daily values. These estimated daily rainfall values were treated the same as observed values if the length of the accumulated period was less than or equal to five days. When the period of accumulated rainfall values was longer than five days, the daily estimates will not be as reliable as those estimated from rainfall totals accumulated over short periods and are flagged as estimated values.

In the previous District rainfall analysis, station-years with up to 150 days of estimated data were included. In this analysis, only station years that have at least a 90 percent probability of including the annual maximum event in the observed values were included. In determining these probabilities, consideration was not only given to the number of missing or estimated days, but also to what month of the year the missing value occurred. The probability that a given daily maximum rainfall event is included in the observed data of a particular year may be represented by the following equation

$$pdmi = [1 - [\sum_{m=1}^{12} \frac{nmd_m}{nd_m} * Pr_m]]*100$$

where

pdmi is the probability, expressed as a percentage, of the daily maximum event being included for a given station year,
nmd is the number of missing days in month m,
nd is the number of days in month m,
Pr is the probability for the maximum event to occur during month m.

Long term rainfall stations representing different regions of the District were examined to determine the likelihood of a maximum rainfall event occurring during a particular month of a year. The frequency distributions for the annual maximum 1- and 3-day duration events appear in Figure 2 and Figure 3 for the Keys, Lower East Coast (LEC), Lower West Coast (LWC), Everglades Agricultural Area (EAA), and Kissimmee Valley. The distributions vary significantly from one region of the District to another. The months of June and September generally have the highest probability for the annual maximum 1- and 3-day duration events to occur while the period of December through March has a minimal probability for occurrence of these same events.

IV. FREQUENCY ANALYSIS

The two-parameter Gumbel distribution was chosen as the probability function for analyzing the series of maximum annual rainfall events. This distribution is essentially log-normal distribution with constant skewness (Chow, Ven T., 1954) and also known as Fisher Tippet Type I distribution. It was chosen because it is widely accepted by practicing professionals, the results are easily compared with other similar analysis including the earlier District analysis and that its use has already been established as a design standard. Its cumulative distribution function, defined as the probability that any outcome in X will be less than or equal to a stated limiting value x, may be expressed as

$$P(X \leq x) = exp\{-exp[-a(x-u)]\}$$

where a and u are a function of the mean and standard deviation.

V. RESULTS

The rainfall depths for the 3-, 5-, 10-, 25- and 100-year return periods for the 1-day and 10-, 25-, and 100-year return periods for the 3-day duration maximum events were computed for each rain gage included in this analysis. The validity of using the Gumbel distribution for this task was tested using the Kolmogorov-Smirnov goodness-of-fit test. In this test, the maximum difference between the stepwise cumulative frequency function derived from the data set and that of the theoretical distribution function determined by the Gumbel method over the range of observed values, is used as a measure of the discrepancy between the theoretical distribution and the observed data.

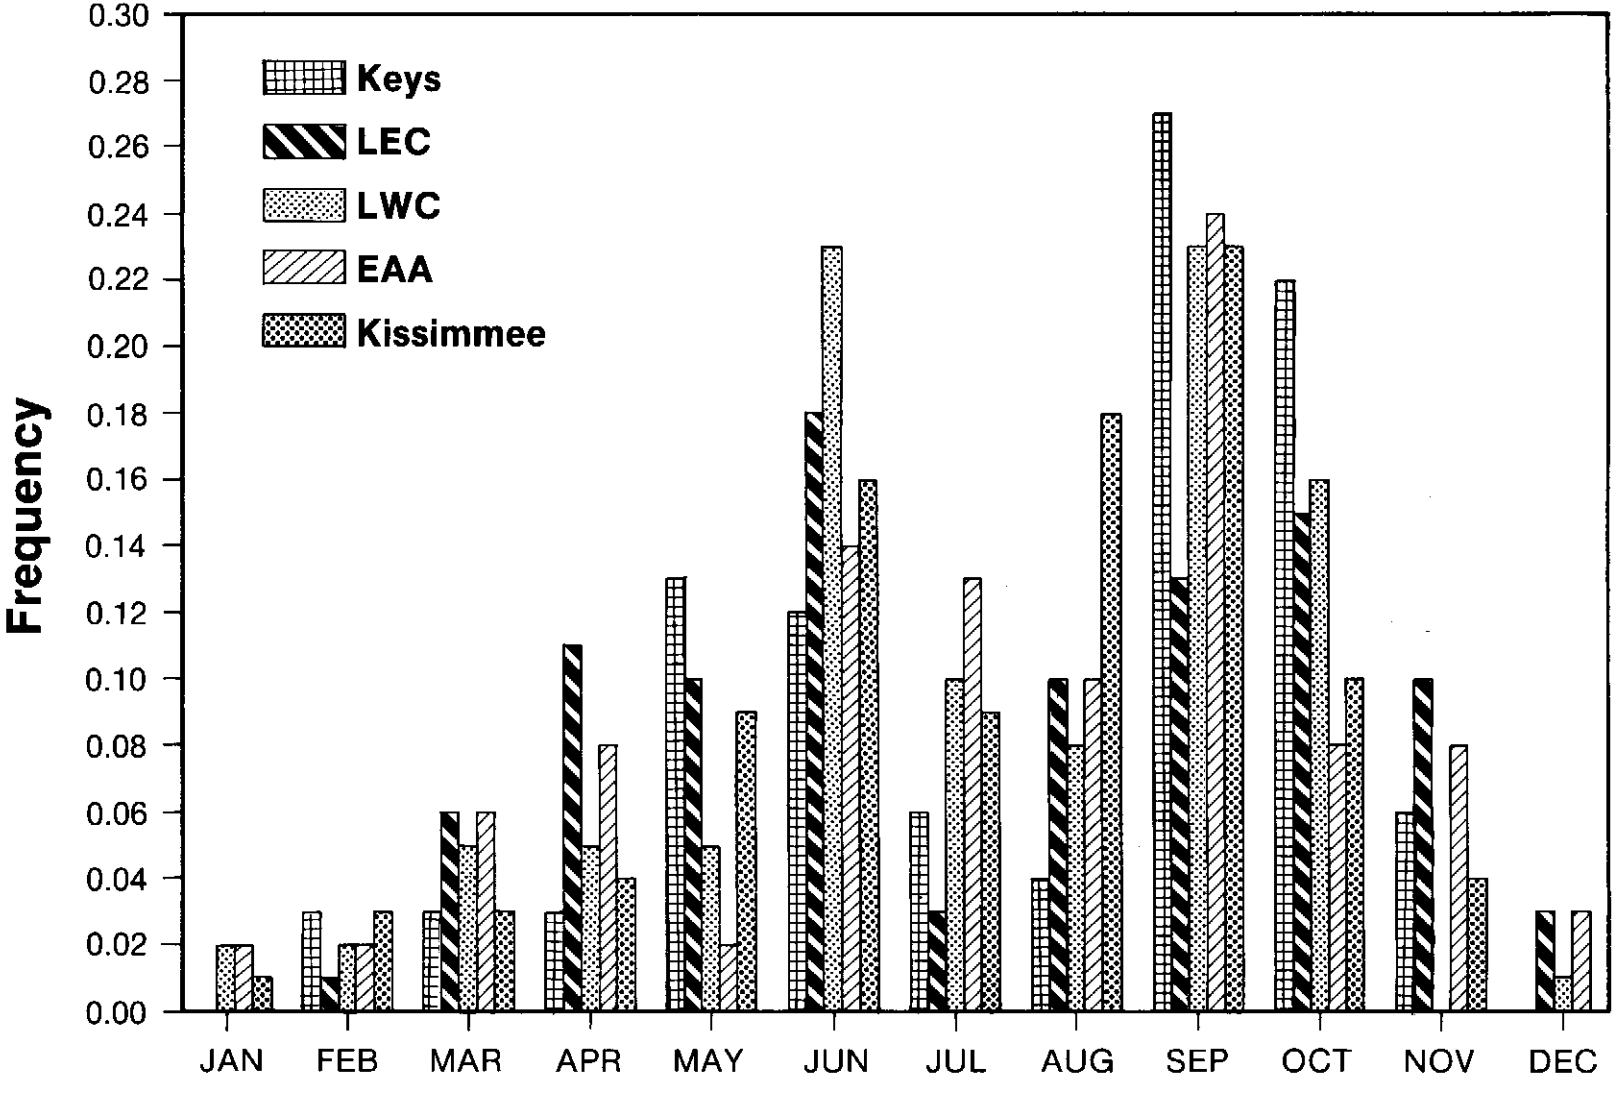

Figure 2. Distribution of Maximum One Day RF Events

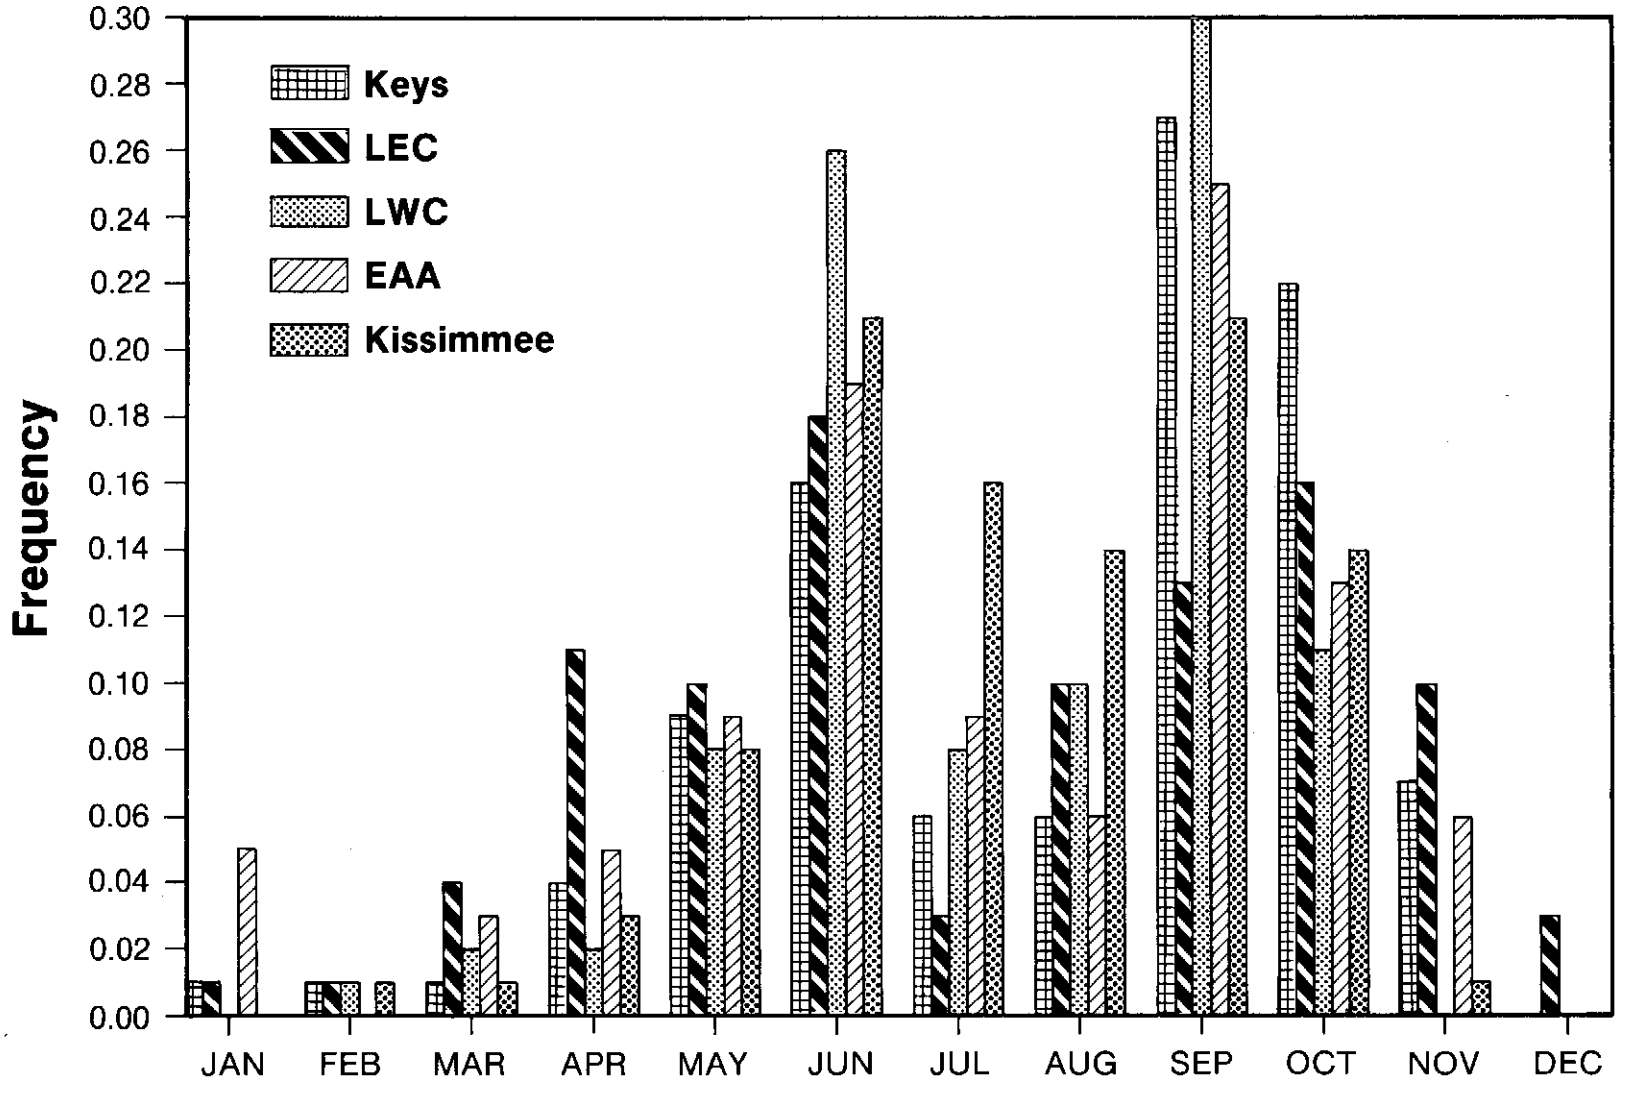

Figure 3. Distribution of Maximum Three Day RF Events

For a specified sample size and the computed maximum difference, a level of significance (α) of the goodness-of-fit can be estimated. For a significance level α, there is a 100 * (1-α)% chance that the population does not follow a specific distribution. In this analysis, 50 percent of the rainfall stations had a significance level of 0.69 or greater for the 1-day maximum events. For the 3-day events, 50 percent of the stations had a significance level of about 0.78. This indicates that over 50 percent of the stations had less than or equal to a 31 percent chance of not following Gumbel distribution for 1-day events, and less than or equal to a 22 percent chance of not following the 3-day events. The test for the 1-day and 3-day events for goodness of fit are independent of each other.

Once rainfall depths were computed, isohyetal maps were produced which illustrate the areal variation in rainfall depths associated with specific return periods and durations. Isohyetals, or lines of equal depths of rainfall, were manually drawn. Large variations in rainfall may occur between stations due to the complex interactions of large scale storm systems with mesoscale systems (1-100 kilometers) such as sea and lake breeze circulations. Rainfall intensities from large scale storm events are often enhanced (or diminished) at locations that normally favor (or resist) the formation of storms due to the mesoscale factors. Examples of regions of enhancement are along the Lower East Coast due to the sea breeze circulations, and to the south of Lake Okeechobee due to lake breeze effects. According to the results of numerical experiments (Pielke,1974), maximum rainfall amounts, due to the sea breeze circulations interacting with the prevailing summertime southeasterly winds, normally would occur several miles inland along the Lower East Coast. These same results indicate the maximum rainfall events on the Lower West Coast would be much closer to the coastline. Examples of regions that would expect lesser maximums would be over and immediately downwind of water bodies where the air is more stable and more generally in the interior regions of South Florida. In summary, the results of this analysis indicate that regions of largest 1- and 3-day duration maximum events occur in many of the same regions that would be greatly enhanced by mesoscale circulations, and illustrate the importance that these circulations have on depicting the location and intensity of maximum storm events.

Other factors affecting the computed values at each rain gauge include the number and period of the years that quality record was available at the gauge, the type of rain gauge being used, the exposure of the rain gauge, and how well the Gumbel distribution fits the data at a particular gauge. It is difficult to account for all the variations that occur between stations. When station values differ significantly from those of nearby stations, the data of this station was checked to verify the cause of the disparity, and to decide whether this gauge indeed included reliable data. In regions that data was sufficient, only stations with greater than 30 years of record were considered.

Figures 4-8 include the 1-day rainfall totals for the 3-, 5-, 10-, 25-, and 100- year return period events, while figures 9-11 include the 3-day rainfall totals for the 10-, 25-, 100-year return period.

VI. SUMMARY

The inclusion of additional rainfall gauges, and the greater number of years of record available, allowed greater reliability and detail to be included in the isohyetal maps than earlier District analysis. The general pattern of larger maximum rainfall events along the coastal regions, particularly the Lower East Coast, still exist with only minor changes in the computed extreme events.

Additional gauges with 20 years record in the interior regions, especially in the lower Kissimmee Valley region, allowed for additional detail to be added to these maps in this region. The last 20 years have tended to be drier in the interior sections of south and central Florida which also lowered the maximum expected values of the computed extreme events in this region.

The precipitation regime over Lake Okeechobee and the surrounding ocean is completely different than that over the land mass of Florida. These maps were generated based on measurements taken over land mass and should not be used to estimate rainfall over Lake Okeechobee or nearby marine areas.
